ABSTRACT

Most nonfatal suicide attempts and suicide deaths occur among patients who deny suicidal ideation (SI) during suicide risk screenings. Little is known about risk factors for suicidal behaviors among such patients. We investigated this in a representative sample of U.S. Army soldiers who denied lifetime SI in a survey and were then followed through administrative records for up to 45 months to learn of administratively-recorded suicide attempts (SA). A novel two-stage risk assessment approach was used that combined first-stage prediction from administrative records to find the subsample of SI deniers with highest subsequent SA risk and then used survey reports to estimate a second-stage model identifying the subset of individuals in the high-risk subsample at highest SA risk. 70% of survey respondents denied lifetime SI. Administrative data identified 10% of this 70% as SI deniers, but it is estimated that of this 10% of SI deniers, 30% of this 70% of SI deniers had the highest subsequent SA risk. Most identified risk factors for suicide in the general population are actually predictors of suicidal ideation (SI; Kessler, Borges, & Walters, 1999; Nock, Kessler, & Franklin, 2016). Knowledge of such risk factors is of limited value in predicting suicidal behaviors in clinical settings, where the focus is on the small proportion of patients with SI who go on to engage in suicidal behavior (ten Have et al., 2009). Little is known about the predictors of these behaviors among patients with SI. Accordingly, researchers have begun to investigate predictors of suicide attempts among ideators (e.g., Nock et al., 2018). However, these investigations do not address the much larger segment of the at-risk population made up of individuals who engage in suicidal behaviors despite denying SI. Some recent studies have reported that the majority of suicide attempts (SAs) and suicide deaths occur among patients who denied SI at previous healthcare appointments or surveys (Louzon, Bossarte, McCarthy, & Katz, 2016; Simon et al., 2013). For the sake of conciseness, we refer to these individuals as “non-ideators,” but it is important to recognize that such individuals are non-ideators by self-report at a single point in time. Some may truly have no history of SI, but others may be concealing their SI. In addition, some may have no SI history as of the time of their healthcare encounter but subsequently develop SI.

The high proportion of SAs made by non-ideators poses a major challenge for healthcare providers who wish to prevent suicide, most of whom assess suicide risk using a gateway question that inquires about SI. Administering an in-depth assessment to all non-ideators is clearly not an option because risk of suicidal behavior is very small in this group, even though the majority of suicide attempts occur among them. Consequently, any action taken to screen the many non-ideators would...
be cost-ineffective; it could also have a negative impact on rapport if a provider continued to insist upon asking suicide-related questions of a patient who had explicitly stated that suicidality was not a concern.

In this paper we present the results of an innovative approach to identifying non-ideators at high risk of suicidal behaviors among US Army soldiers. The approach involves a two-stage assessment process (Kessler et al., in press). The first stage takes advantage of the extensive amount of administrative data available for soldiers to develop a prediction model that can be implemented passively to identify the small proportion of non-ideators who have elevated SA risk. Although predictions based on this first-stage model are incapable of identifying the small proportion of non-ideators who have sufficiently high SA risk to warrant preventive intervention, previous research suggests that such a model can identify a large proportion of soldiers who are at low SA risk for exclusion from further assessment (Ursano et al., 2016). The remaining non-ideators are then the focus of further analysis. These soldiers are administered a series of self-report questions that are used to estimate a second-stage model to identify non-ideators at highest SA risk. This two-stage approach limits the number of non-ideators required to receive this self-report assessment in an effort to keep patient burden to a minimum.

We apply this two-step approach here to predict nonfatal SAs among non-ideators in a large sample of U.S. Army soldiers who participated in the main survey component of the Army Study to Assess Risk and Resilience in Servicemembers (STARRS; Ursano et al., 2014). The likelihood of denying SI is high in this population given that reporting SI could have negative career implications. Yet the need to implement suicide prevention programs in this population is particularly urgent given that the Army suicide rate climbed steeply in recent years (Schoenbaum et al., 2014) and preventing suicide represents a major priority and area of investment for the Army (Department of the Army, 2012).

1. Method

1.1. Participants

Participants were drawn from the STARRS Consolidated All-Army Survey (AAS). We focus on the 27,501 Regular Army soldiers who participated in that survey, who agreed to have their survey data linked to their Army administrative data, and whose survey dates were non-missing. The consolidated AAS is made up of three component surveys. The largest of the three was a representative survey of non-deployed soldiers no longer in Initial Military Training carried out in 2011–2012 that contributed 17,462 respondents to the consolidated AAS (95.0% survey consent rate, 97.3% survey completion rate among consenters, 61.3% administrative data linkage consent rate among survey completers). The second was a survey of soldiers from three Brigade Combat Teams preparing to deploy to Afghanistan in 2013 that contributed 8558 respondents to the consolidated AAS (98.7% survey consent rate, 99.2% survey completion rate among consenters, 90.9% administrative data linkage consent rate among survey completers). This second survey was added because soon-to-deploy soldiers were under-represented for logistical reasons in the first survey. The third was a survey of soldiers in transit to and from mid-deployment leave in Kuwait in 2013 that contributed 3987 respondents to the consolidated AAS (80.9% survey consent rate, 86.5% survey completion rate among consenters, 55.6% administrative data linkage consent rate among survey completers). This third survey was added because none of the respondents in the first two surveys were currently deployed. The three surveys are described in detail elsewhere, along with a description of the methods used for data collection and for weighting the combined data to adjust for differential probabilities of selection and discrepancies between the sample and the population on a range of administrative variables (Kessler et al., 2013; Millner et al., 2018). Procedures for obtaining informed consent and collecting data in all three surveys were approved by the Human Subjects Committees of the Uniformed Services University of the Health Sciences, the Institute for Social Research at the University of Michigan, and all other collaborating organizations. The analyses presented here focus only on soldiers who responded in the negative to two survey questions about active (“Did you ever in your life have thoughts of killing yourself?”) and passive (“Did you ever wish you were dead or would go to sleep and never wake up?”) SI.

1.2. Measures

Outcome measure: Post-survey suicide attempts. The outcome variable, presence of a suicide attempt subsequent to AAS survey completion, was assessed prospectively using administrative data available through December 2014 from the Army STARRS Historical Administrative Data System (HADS). The HADS integrates records from numerous data sources, four of which include information on SA: (i) the Department of Defense Suicide Event Report (DoDSER; Gahm et al., 2012) and DoDSER’s predecessor (i.e., the Army Suicide Event Report; ASER; Gahm et al., 2012); (ii) the Military Health System Data Repository; (iii) the Theater Medical Data Store; and (iv) the TRANSCOM (Transportation Command) Regulating and Command and Control Evacuating System. These databases together contain comprehensive healthcare encounter information from military and civilian treatment facilities, deployed operations, and aeromedical evacuations. The data used to define SA (described in more detail elsewhere; Ursano et al., 2015) included attempts documented in DoDSER records and International Classification of Diseases, Ninth Revision, Clinical Modification codes for self-inflicted poisoning or injury with suicidal intent (codes E950-E958) from any of the other databases. Information was recorded on the date of the first SA of every AAS respondent subsequent to the date of survey.

Administrative predictors of suicide attempts. We included in our prediction models a number of basic socio-demographic variables (age, sex, race/ethnicity, education, marital status, number and ages of children, religious denomination, country of origin) and Army career variables (years since enlistment, rank, current deployment status, number of prior combat deployments, major command) that are available for all soldiers in Army administrative records and that have shown associations with suicidal behavior in some literature. We also included in the models a composite score representing the predicted probability of suicide fatality (not attempt) developed from a comprehensive historical analysis of HADS data for the entire Army over the years 2004–2009. In other words, we assessed whether the predicted probability of death by suicide was a predictor of SA, as no comparable historical model exists for SA. That score combined predictions from separate models reported in earlier publications for suicides among soldiers with a history of psychiatric hospitalization (Kessler et al., 2015) and other soldiers with a history of outpatient treatment for mental health problems (Kessler et al., 2017) along with an unpublished model developed using similar methods for soldiers with no history of inpatient or outpatient treatment of mental health problems. Close to 500 administrative variables were considered for inclusion in these models and between 12 and 20 were selected as final predictors after adjusting for the possibility of false positives. The coefficients were then applied to HADS data available for each AAS respondent as of the month prior to completion of the AAS survey in 2011–2013 to generate a predicted probability of subsequent suicide. The predicted probabilities were standardized to a mean of 0 and variance of 1 in the subsample of respondents who reported no history of SI in the survey to facilitate interpretation of the regression coefficient associated with that predictor. By adding this composite historical variable into the model, we were able to aggregate a great deal of risk information from the HADS in a single variable, thereby preserving statistical power. However, it remained necessary to include additional predictors (i.e., the socio-demographic and career variables mentioned above) because
suicide fatality and SA are distinct events with differing risk factors.

**AAS self-reported predictors of suicide attempts.** AAS self-reports were used as predictors of SA in a number of previous STARRS analyses that used retrospective self-reports of lifetime SA as the outcome variable (Millner et al., 2017; Millner et al., 2018; Nock et al., 2018). Seven categories of AAS self-reports that were found in these studies to be significant predictors of SA were considered in the prospective model here: 8 predictors for lifetime mental disorders, 4 for severity of 30-day mental disorder symptoms (i.e., in the 30 days prior to the survey), 29 for 30-day exposure to traumatic events (e.g., sexual assault, combat exposure), 5 for severity of chronic stressors at the time of survey (e.g., in such areas as finances and romantic relationships), 3 for traumatic brain injury (both lifetime exposure and severity of 30-day post-concussive symptoms), and 6 for social support-related factors.

### 1.3. Data analysis

Fig. 1 depicts the stages of the analytic process, including which subset of the AAS sample was analyzed at each stage.

**First-stage analysis.** The goal of the first stage of data analysis was to predict SA from administrative data available at the time of the survey. As noted above in the section on measures, we used for this purpose a composite suicide prediction score based on an earlier historical analysis of the HADS data for the years 2004–2009 in addition to basic socio-demographic and Army career variables available for each AAS respondent as of the month of survey. Discrete-time survival analysis with person-month as the unit of analysis, beginning with separate models for each of the seven categories of predictors, controlling for seasonality and number of months since the survey. Predictors with significant univariate associations with SA were combined to generate within-category multivariate models, which were then trimmed to exclude nonsignificant predictors. The predictors in each of these within-category multivariate models were then combined into a final second-stage model.

To evaluate the possibility of over-fitting, we used 20 replicates of 10-fold cross-validation (10F-CV; James, Witten, Hastie, & Tibshirani, 2013).
2013) to generate estimates of out-of-sample performance based on the final second-stage model. 10F-CV is an approach in which model prediction accuracy is assessed in a sample of people separate from the sample in which the model was estimated by dividing the sample into 10 subgroups of equal size, estimating the model 10 separate times leaving out cases in one subsample each time, and using the coefficients from the model estimated when a given subsample was excluded to make predictions only for that omitted subsample. A pooled ROC curve is then estimated based on these combined predicted values to estimate how well the model would predict if it were applied to a new sample. Prior simulations have shown that this method yields fairly accurate estimates of out-of-sample performance of prediction models when model results are evaluated in the same sample as the one in which the model was estimated, but that performance can be improved in samples with sparse outcomes, which is the type of sample we have here, if the 10F-CV is repeated 20 separate times with independent designation of subsamples (i.e., 20 replications of the sample being divided into 10 random subsamples) and results averaged across these replicates (Smith, Seaman, Wood, Royston, & White, 2014). This is what we did here.

This second-stage discrete-time survival model assumed that the joint predictive effects of the risk factors were linear and additive. However, most theories of suicidal behaviors hypothesize that non-additivities exist among risk factors (Selby, Joiner, & Ribeiro, 2014). To address this issue, we used the super learner (SL) ensemble machine learning algorithm (van der Laan, Polley, & Hubbard, 2007) to apply a series of interactive models to the predictors in the final stage-two model to find the best-fitting specification. In addition to a penalized additive model (elastic net; Zou & Hastie, 2005), the non-additive model results are evaluated in the same sample as the one in which the model was estimated, but that performance can be improved in samples with sparse outcomes, which is the type of sample we have here, if the 10F-CV is repeated 20 separate times with independent designation of subsamples (i.e., 20 replications of the sample being divided into 10 random subsamples) and results averaged across these replicates (Smith, Seaman, Wood, Royston, & White, 2014). This is what we did here.

2. Results

2.1. Prevalence of suicide attempts separately among AAS ideators and non-ideators

Lifetime SI was reported by 13.2% (n = 3647 of 27,501) of AAS respondents. Subsequent SAs were administratively recorded for 243 of the AAS respondents, a weighted 32.5% of whom (n = 75) reported SI in the survey and 67.5% (n = 168) of whom did not. The association between survey reports of SI and subsequent administratively-recorded SA was statistically significant (OR 3.0, 95% CI 1.8–5.0); the SA rate among those who denied SI was 124.8 per 100,000 person-years compared to 378.0 per 100,000 person-years among those who reported SI.

2.2. First-stage model: predicting suicide attempts from administrative data

We focused on the 86.8% of AAS respondents (n = 23,854) that reported no lifetime SI in the survey. These respondents were followed administratively for a total of 718,055 person-months until either the first SA after the survey was recorded (subsequent SAs were ignored in the analysis), they separated from service, they died, or it was December 2014, whichever came first. Suicide fatalities, n = 11, were considered deaths rather than SAs. This was done based on evidence that the predictors of nonfatal SA are quite different from the predictors of suicide death, the most striking example being the much higher suicide death rate among men than women but much higher nonfatal SA rate among women than men. A case might be made that suicide deaths should be considered SAs and included in the analysis, although results are unlikely to have been affected strongly due to the small number of suicide deaths in the sample.) There were 168 person-months in which an attempt took place among non-ideators; therefore, sampling of 20 control person-months for each attempt resulted in a total analytic sample of 3528 (i.e., 168*20 + 168) person-months.

The final first-stage model appears in Table 1. (Detailed results of the two preliminary models are available on request.) Odds of administratively-recorded SA were inversely associated with age and positively associated with racial/ethnic minority status, having less than college education, being a first-generation American, enlisted rank, number of prior deployments, and the standardized HADS composite suicide prediction score.

The area under the ROC curve (AUC) of the model was 0.82. An inspection of PPV by decile of predicted risk showed a clear

Note. Based on a discrete-time person-month survival model that subsampled a probability sample of 20 controls for each suicide attempt and weighted the control person-months by the inverse of their probability of selection to reconstruct their population proportions, resulting in a total of 3528 person-months. Model OR’s control for seasonality and months since survey. Predictor values were defined as of the month of survey.

*p < .05.

* All estimates are percentages unless labeled otherwise.

† Soldiers are defined as being first generation if either they were born outside the U.S. or both their parents were born outside the U.S.

‡ This variable was coded in the range 0–4. Soldiers with more than 4 deployments were coded 4 to stabilize the regression coefficient.

§ This is a standardized transformation of a composite measure to generate a predicted-probability-of-suicide from HADS administrative data based on an earlier analysis of the HADS database for the years 2004–2009. See text for further detail.
months since survey, and number of prior deployments (the variables for each of the seven categories of AAS predictors described above in 2.3. Second-stage model: predicting suicide attempts from AAS survey data model-building on the 30% of observations with highest predicted risk. were in the highest risk decile (SN = 50.5%) and 81.2% in the three lower-risk deciles were all below the rate in the general U.S. population 100,000 person-years, as shown in Table 2. The cumulative PPVs for the lower risk deciles, where the SA rate was in the range of 0.04–180.0 per 100,000 person-years in each decile. Values reflect weighted data. As explained in the text, the 20:1 sampling of control person-months to attempt person-months, followed by selection of only those person-months of participants who denied lifetime suicidal ideation, resulted in a total of 3528 person-months. We also used all variables included in this final model (not just those that were significant when entered together) to estimate an SL ensemble machine learning model that allowed for nonlinearity and interactions among the predictors to see if the performance of the final logistic model could be improved on by relaxing the linearity and additivity assumptions implicit in that model. This entire series of procedures was applied five separate times in calculating the SF-CV SL AUC, which was 0.83.

We inspected the ROC curves for the cross-validated second-stage and SL models, shown in Fig. 2, and used these to guide the creation of relatively homogeneous risk strata, which are shown in Table 4. The SL model had substantially better out-of-sample performance than the original second-stage model. The highest risk stratum in the SL model, which consisted of the 5% of high-risk soldiers (i.e., 5% of 30% = 1.5% of all non-ideators) with highest cross-validated predicted SA risk, had a PPV of 3273.6 per 100,000 person-years and a SN of 48.1% (compared to PPV = 702.0/100,000 person-years and SN = 10.1% in the cross-validated second-stage model). The second highest risk stratum in the SL model consisted of another 5% of high-risk soldiers, who had a PPV of 514.1 per 100,000 person-years and a SN of 7.4%, resulting in 55.5% of all SAs occurring among the 10% of soldiers at highest risk (within this 30% high-risk sample already selected by the administrative model, i.e., 3% of all non-ideators). It is striking that the 50% of soldiers with lowest predicted risk in the high-risk sample had PPV (61.6/100,000 person-years) considerably lower than in the general U.S. population (Piscopo et al., 2016), indicating that despite their classification as higher-risk based on the first-stage administrative predictors, the AAS survey data subsequently showed that they were actually lower-risk.

3. Discussion

The goal of this study was to determine the feasibility of developing a two-step procedure for identifying non-ideators at risk of SA among U.S. Army soldiers who denied SI. The study had three key findings. First, consistent with recent prospective studies in other settings (Louzon et al., 2016; Simon et al., 2013), the preponderance of attempts (67.5%) occurred among soldiers who denied any lifetime SI. This is especially notable given that soldiers who completed the survey were assured their responses would be confidential, which should have reduced motivation to conceal information. It may, then, be a robust phenomenon that most SAs are made by non-ideators, at least among Army soldiers.

Second, the two-stage procedure showed the potential for strong predictive performance while limiting burden on patients and providers. The first-stage model was able to classify 70% of non-ideators as having minimal risk of SA based solely on administrative data. The second-stage model, which was based on responses to a limited number of self-report survey questions, was able to identify an additional 15% of non-ideators as minimal-risk (i.e., 50% of 30%) and classify the remainder as higher-risk, with almost half of all attempts among non-ideators made by the stratum containing the 3% (i.e., 10% of 30%) at highest risk.

This model performance is particularly impressive given that it might be expected that predicting attempts among soldiers who denied SI would be more difficult than predicting attempts among ideators for several reasons. First, individuals who deny SI may be less willing or able to report risk factors accurately. Second, the characteristics of ideation and other suicidal behaviors are strong risk factors for transitioning from ideation to attempt (Nock et al., 2018), whereas such predictors do not exist for non-ideators. Finally, it is possible that attempts among non-ideators are more frequently driven by situational variables that unfold quickly, whereas the drivers of attempts among ideators may be more stable or chronic (Millner, Lee, & Nock, 2017). It is striking that despite these challenges we were able to predict attempts among non-ideators with good accuracy.

A third key finding is that risk factors for SA among non-ideators in the Army are largely comparable to predictors found in other studies, although additional research is needed to clarify this by directly comparing ideators and non-ideators. Several of the risk factors found here correspond to predictors found among all Army soldiers in previous STARSS studies, including age, education, rank, deployment history, and mental illness history (e.g., Millner et al., 2017; Nock et al., 2014; Ursano et al., 2015; Ursano et al., 2016). The elevated risk of SA among racial/ethnic minority non-ideators contrasts with the finding in some
Table 3

Note. The sample for this model represents the 30% high-risk subsample of the full sample shown in Table 1 and has a total of 1248 person-months. See the text for a description of the method used to define the high-risk subsample. Model estimates reflect weighted data. Model OR's control for seasonality and months since survey. Predictor values reflect information at the month of survey. 

\(^a\) All estimates are percentages unless labeled otherwise.

\(^b\) Current mental disorder symptoms is the standardized sum of the 4 scores for severity of depression, anxiety, irritability, and PTSD. Higher values reflect more severe symptoms.

\(^c\) Recent interpersonal problems is a summary measure of four individual events: separation/divorce from spouse/partner, spouse/partner cheated, betrayal by someone close, and serious ongoing arguments/break-up with friend/relative. Values ranges from 0 to 3, with 0 indicating no recent interpersonal problems (75.1% of sample), 1 indicating exactly 1 (13.0% of sample), 2 indicating exactly 2 or 3 (9.9% of sample), and 3 indicating exactly 4 (2.0% of sample).

\(^d\) Recent general stressors is the standardized sum of the maximum scores in each of five life areas: financial situation/career, health, love life, relationship with family and health of loved ones, and problems with unit. Higher values reflect more severe life stress.

\(^e\) Any other TBI included more-than-mild TBI that occurred 6 or more years ago and any mild or any less-than-mild TBI.

\(^f\) This is a standardized transformation of a composite measure to generate a predicted-probability-of-suicide from HADS administrative data based on an earlier analysis of the HADS database for the years 2004–2009. See text for further detail.

The circumstances in which the survey was administered might limit the generalizability of these findings. As noted previously, participants in this study were guaranteed confidentiality when asked about both SI and risk factors. This would not be the case in a healthcare setting nor in any other setting in which self-reported information might be used to determine the need for further screening or intervention. And in the Army, such information could have negative career consequences. Higher rates of concealing ideation might consequently be expected when applying these findings in clinical practice in the military and possibly in other settings. There might also be some distortions in self-reports about other risk factors and in the predictive model based on such differences. As a result, any efforts on the part of

---

![Fig. 2. Receiver operating characteristics (ROC) curve for 20 replicates of tenfold cross-validated logistic regression versus five-fold cross-validated SuperLearner in predicting prospective suicide attempts among high-risk subsample of non-ideators.](image)
...available for soldiers (e.g., www.accurint.com). One way of advancing our understanding of potentially effective preventive interventions for high-risk soldiers who deny SI would be to carry out in-depth suicide-focused assessments of need for services with the Army to develop a system to collect self-report data of the sort we used to develop our model would need to experiment in order to determine the best way to collect such information and the strength of the resulting prediction model.

A related limitation in applying our results to a civilian population is that the rich administrative data available for all soldiers are either not available or not relevant for the general population. Given this limitation, a promising direction for this line of work in future research that uses panel survey data could address this limitation by using self-report measures or performance-based measures.

An additional limitation is that the model was used to predict only the subset of SAs that come to medical attention. We know from comparisons of STARRS survey data with administrative data linked to survey reports that a substantial proportion of the SAs reported by soldiers in their surveys are not recorded in administrative records. And there are presumably yet other SAs that are both denied in surveys and not recorded in administrative records. Access to comprehensive data on all SAs would presumably allow a model to be created that would improve on the accuracy of our model in projecting future SA risk. Future research that uses panel survey data could address this limitation by using information reported in the baseline survey to predict the subsequent occurrence of SAs either reported in subsequent surveys and/or recorded in administrative records.

An additional limitation of this study is that, although strong, the predictive performance of the model is far from perfect. Enriching the feature set of previously-existing administrative data in the first-stage model could shrink the proportion of individuals who would require second-stage assessments. For example, the first-stage model could use text scraped from electronic medical record notes or social media postings (Ben-Ari & Hammond, 2015; Bryan et al., 2018). Performance of the second-stage model might also be improved, since it is unlikely that the questions asked in the AAS happened to include the perfectly optimal items for predicting suicidal behavior. Future investigations could add other self-report measures or performance-based measures such as the Suicide Implicit Association Test, which in one study predicted SAs beyond patients’ report of ideation and likelihood of re-attempt (Nock et al., 2010). Further, the present study did not differentiate between those who attempted suicide soon after survey administration and those who attempted suicide several years later. The ideal model may differ for individuals at imminent versus long-term risk. Developing models with a variety of time horizons could improve accuracy and could inform the nature of the intervention offered (e.g., crisis intervention versus longer-term skills training or psychotherapy).

Despite this study’s limitations, we believe the strategy presented here is unique in suggesting a practical way to assess SA risk among non-ideators. The optimal way to do so is yet to be determined, though, because the variables available to us are unlikely to be the best ones in building models and we do not know either the ideal setting or the ideal frequency for this assessment. As one possible implementation in the Army, though, one could imagine a scenario in which all soldiers who report for routine healthcare visits are asked about SI, perhaps on a tablet or computer while in the waiting room. For those who deny ideation, the tablet could compute the risk score based on the first-stage algorithm by pulling the soldier’s administrative data (i.e., with no additional input). Soldiers deemed at minimal risk based on the first-stage administrative model would receive no further assessment, whereas soldiers at higher risk would be administered an additional battery of self-report questions and a second-stage algorithm would be applied to those responses to determine the need for a more in-depth clinical assessment by a healthcare provider.

The question remains, then, what steps a clinician should take when faced with an at-risk individual who denies ideation after an in-depth clinical assessment. Appropriate interventions for non-ideators have yet to be identified; the best-supported treatments for reducing SA risk among servicemembers (e.g., Rudd et al., 2015) involve directly treating suicidal thoughts and behaviors, but such treatments are obviously not applicable for individuals who deny ideation. However, the risk factors for attempts found in this study do hint at possible targets for intervention among U.S. Army soldiers who deny ideation but are predicted to be at high risk. If these risk factors play a causal role in SAs (which would need to be confirmed in future studies), then treating those risk factors should be a viable strategy for reducing risk. Notably, we found that meeting criteria for one or more common mental disorders is a risk factor for SA. Being bullied was another significant predictor. Interventions for treating common mental disorders exist, as do training programs also exist for coping with interpersonal stressors. Such interventions might reduce SAs among high-risk soldiers who deny ideation. Given the observational nature of this study and the lack of evidence for the effects of such interventions on SAs, though, these suggestions remain speculative.

Once way of advancing our understanding of potentially effective preventive interventions for high-risk soldiers who deny SI would be to carry out in-depth suicide-focused assessments of need for services with...
such soldiers and use the information obtained in such assessments both to guide treatment planning and to develop third-stage models that might be used for clinical decision support in selecting optimal treatments keyed to the varying risk factors of high-risk soldiers (Kessler et al., in press). Future research is also needed to replicate our findings regarding optimal first-stage and second-stage predictors and to investigate the ideal frequency and setting for assessment in order to pinpoint soldiers at high risk of suicidal behaviors for more in-depth clinician assessments and targeted preventive interventions.

Funding

Army STARRS was sponsored by the Department of the Army and funded under cooperative agreement number U01MH087981 (2009–2015) with the U.S. Department of Health and Human Services, National Institutes of Health, National Institute of Mental Health (NIMH). Subsequently, STARRS-LS was sponsored and funded by the Department of Defense (USUHS grant number HU0001-15-2-0004). A complete list of Army STARRS publications can be found at http://www.STARRS-LS.org. This work also was supported in part by funding from the Military Suicide Research Consortium (MSRC), an effort supported by the Office of the Assistant Secretary of Defense for Health Affairs (Award W81XWH-10-2-0181). Opinions, interpretations, conclusions, and recommendations are those of the authors and are not necessarily endorsed by the MSRC, the Department of Health and Human Services, NIMH, the Department of the Army, the Department of Veterans Affairs, or the Department of Defense.
